Mycolactone activation of Wiskott-Aldrich syndrome proteins underpins Buruli ulcer formation

Laure Guenin-Macé, … , Marie-France Carlier, Caroline Demangel

Research Article   **Infectious disease**

Mycolactone is a diffusible lipid secreted by the human pathogen *Mycobacterium ulcerans*, which induces the formation of open skin lesions referred to as Buruli ulcers. Here, we show that mycolactone operates by hijacking the Wiskott-Aldrich syndrome protein (WASP) family of actin-nucleating factors. By disrupting WASP autoinhibition, mycolactone leads to uncontrolled activation of ARP2/3-mediated assembly of actin in the cytoplasm. In epithelial cells, mycolactone-induced stimulation of ARP2/3 concentrated in the perinuclear region, resulting in defective cell adhesion and directional migration. In vivo injection of mycolactone into mouse ears consistently altered the junctional organization and stratification of keratinocytes, leading to epidermal thinning, followed by rupture. This degradation process was efficiently suppressed by coadministration of the N-WASP inhibitor wiskostatin. These results elucidate the molecular basis of mycolactone activity and provide a mechanism for Buruli ulcer pathogenesis. Our findings should allow for the rationale design of competitive inhibitors of mycolactone binding to N-WASP, with anti–Buruli ulcer therapeutic potential.

Mycolactone is a diffusible lipid secreted by the human pathogen *Mycobacterium ulcerans*, which induces the formation of open skin lesions referred to as Buruli ulcers. Here, we show that mycolactone operates by hijacking the Wiskott-Aldrich syndrome protein (WASP) family of actin-nucleating factors. By disrupting WASP autoinhibition, mycolactone leads to uncontrolled activation of ARP2/3-mediated assembly of actin in the cytoplasm. In epithelial cells, mycolactone-induced stimulation of ARP2/3 concentrated in the perinuclear region, resulting in defective cell adhesion and directional migration. In vivo injection of mycolactone into mouse ears consistently altered the junctional organization and stratification of keratinocytes, leading to epidermal thinning, followed by rupture. This degradation process was efficiently suppressed by coadministration of the N-WASP inhibitor wiskostatin. These results elucidate the molecular basis of mycolactone activity and provide a mechanism for Buruli ulcer pathogenesis. Our findings should allow for the rationale design of competitive inhibitors of mycolactone binding to N-WASP, with anti–Buruli ulcer therapeutic potential.

Introduction

Mycolactone is an original polyketide metabolite synthesized by *Mycobacterium ulcerans*, the causative agent of Buruli ulcer (1). The life cycle of *M. ulcerans* is not fully understood, but there is evidence that Buruli ulcer is transmitted via insect bites (reviewed in ref. 2). Lesions typically start as a subcutaneous nodule, edema, or plaque that enlarges over time. The epidermis eventually breaks down to reveal a characteristic wound bordered by necrotic tissues (3). Mycolactone is essential for bacterial virulence and, in intradermally injected animal models, is sufficient to induce Buruli ulcer–like lesions that are marked by extensive necrosis and lack of inflammation (4). In vitro, mycolactone diffuses passively into the cytoplasm of mammalian cells to induce apoptotic cell death, although with highly variable efficacy (5). Anchorage-dependent cells are the most susceptible to mycolactone toxicity, which proceeds through cytoskeletal rearrangements and detachment (6–8). Intriguingly, at noncytotoxic doses, mycolactone also alters key functions of immune cells, such as cell trafficking and TLR-induced cytokine production (9–15). How mycolactone mediates these effects has thus far remained unknown.
Given the pivotal role played by the cytoskeleton in controlling many biological processes, we reasoned that a common denominator of the activities described above could be alterations in actin dynamics. Our investigations have led us to identify Wiskott-Aldrich syndrome protein (WASP) and neural WASP (N-WASP) as molecular targets of mycolactone. Along with Scar/WAVE-1–WAVE-3, WASP and N-WASP constitute a family of scaffold proteins transducing a variety of signals into dynamic remodeling of the actin cytoskeleton, via interaction of their C-terminal verprolin-cofilin-acidic (VCA) domain with the ARP2/3 actin-nucleating complex (reviewed in ref. 16). In basal conditions, WASP and N-WASP are autoinhibited by intramolecular interactions sequestering the VCA domain from ARP2/3. Binding of activated GTPases or phosphoinositide lipids to N-terminal target sequences triggers conformational changes resulting in release of the VCA, thereby enabling binding and activation of ARP2/3 (reviewed in ref. 17). WASP expression is restricted to hematopoietic cells, with loss- or gain-of-function mutations leading to a complex syndrome of immune defects, whereas N-WASP is more widely expressed (18). These proteins play a crucial role at the cellular level in endocytosis (19), immune synapse formation, signaling, adhesion, and migration (16, 20). At the tissue level, they are crucial for the maintenance of skin integrity, as shown by distorted junctions of N-WASP–depleted epithelial cells (21, 22) and spontaneous ulcerations in mice with conditional N-WASP deletion in the skin (23).

Using a combination of biochemical assays, cellular imaging, and animal models, we here revealed that mycolactone mimics

physiological signals normally delivered by Rho GTPases to hijack WASP-dependent actin polymerization. We showed that mycolactone-induced activation of N-WASP in epithelial cells and the consequent dynamic rearrangements of the actin cytoskeleton dramatically impaired the integrity of the epidermis, thus providing a molecular mechanism underpinning Buruli ulcer pathogenesis.

Results

Mycolactone binds selectively to the WASP/N-WASP regulators of actin polymerization. To analyze the effect of mycolactone on the cytoskeleton, we selected the HeLa cell line, as a model of anchorage-dependent cells of the human epithelial system, and the Jurkat cell line of human T lymphocytes, to reflect the activity of mycolactone on nonadherent, immune cells. Cells were treated with mycolactone for 5–60 minutes, then fixed and stained with fluorophore-coupled phalloidin. As shown in Figure 1A, HeLa cells exposed to mycolactone for 30 minutes produced filopodes, whereas a 5-minute treatment induced the transient formation of a large lamellipode in Jurkat cells. These observations showed that mycolactone affects the cytoskeleton in a cell-specific manner, with the filopode and lamellipode induction suggesting a modulation of actin dynamics downstream of the RAC/CDC42 GTPases. To address this possibility, we investigated a possible interaction of mycolactone with WASP, N-WASP, or p21-activated kinase (PAK), since they mediate RAC/CDC42 signals to the actin cytoskeleton via their interactive binding (CRIB) domain (Figure 1B). Mycolactone was modified to allow covalent attachment of a biotinyl group at the end of its polyunsaturated side chain. The resulting adduct retained the biological properties of native mycolactone, as evidenced by its cytopathic and immunosuppressive activity on HeLa and Jurkat cells, respectively (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI66576DS1). Biotinylated mycolactone was then used in ELISA to assess binding to the GTPase-binding domain (GBD) of WASP, N-WASP, and PAK, expressed as glutathione S-transferase (GST) fusion proteins (Figure 1C, CR1 constructs). Strikingly, mycolactone bound significantly and dose-dependently to the CR1 domain of WASP and N-WASP, but not to that of PAK (Figure 1D, left).

To investigate the respective contributions of the lysine-rich basic region (BR) and the CRIB domain in CR1, we measured the reactivity of a series of constructs missing part or all of these motifs (Figure 1C). In both WASP and N-WASP, mycolactone binding was abolished when the BR was incomplete (Figure 1D, middle). However, the presence of the BR was not sufficient, as shown by the lack of reactivity of CR3 in N-WASP. Residues located upstream

of the BR were not required and even diminished interaction, as evidenced by the highest reactivity of CR7 compared with CR1 and CR6 (Figure 1D, middle and right). Neither of the complementary CR7 subfragments CR8 and CR11 showed binding to mycolactone. Reactivity was partially restored with CR10, which indicates that an intact 222–276 region in N-WASP is essential. In contrast, CR9 showed no reactivity to mycolactone, further demonstrating that the BR/CRIB region is necessary but not sufficient for optimal binding. However, addition of the CRIB domain to CR10 (i.e., CR2) did not improve reactivity. Together, these results suggested that mycolactone binding to N-WASP involves a primary interaction site situated downstream of the CRIB in the 222–276 region and a secondary site in the BR. Of all the constructs examined, CR1 in WASP and CR7 in N-WASP constituted the minimal linear domains binding mycolactone, and were therefore selected for further studies. The dissociation constants of mycolactone for CR1 and CR7 were determined by a titration assay based on tryptophan fluorescence. They were found to be comparable, in the 20- to 70-nM range (Supplemental Figure 2).

Mycolactone binding to WASPs results in CDC42-independent hyperactivation. Since WASP and N-WASP use the ARP2/3 complex to stimulate actin assembly via filament branching, once the autoinhibition is relieved by binding of GTP-loaded CDC42 (CDC42-GTP) (24, 25), we next used a pyrene fluorescence assay to examine whether mycolactone affects N-WASP activity. We found that mycolactone induced dose-dependent stimulation of the actin polymerization activity of N-WASP (Figure 2A). The maximum rate of actin assembly showed a saturation behavior, with an equilibrium dissociation constant of 170 nM (Supplemental Figure 3). In agreement with the above observation that mycolactone bound the GBD of N-WASP, mycolactone was unable to promote ARP2/3-dependent polymerization of actin in the absence of N-WASP, nor could it stimulate a N-WASP mutant lacking the GBD (data not shown). CR7 inhibited mycolactone-induced activation of N-WASP in a dose-dependent manner, with a half-effect of 0.25 μM at 32 nM N-WASP (Figure 2B), which indicates that mycolactone binds CR7 and N-WASP with similar affinity. As controls, CR2 and CR3 did not modify the mycolactone-induced activation of N-WASP (Figure 2C).

Binding of CDC42-GTP to the GBD in WASP/N-WASP triggers transition from an autoinhibited state, in which the VCA domain is sequestered by intramolecular binding to the GBD, into an active state, where released VCA can bind ARP2/3 (24, 25). Since the primary interaction site of mycolactone (222–276 in N-WASP) contains most of the residues accounting for the autoinhibited fold (25), we investigated whether mycolactone affects intramolecular interactions. WASP CR1 was immobilized on beads and used to capture recombinant VCA. The resulting complex was then incubated with mycolactone, and VCA dissociation was monitored by pulldown assay. A dose-dependent release of CR1-bound VCA was induced by mycolactone (Figure 2D), which demonstrated that mycolactone disrupts WASP autoinhibition.

We then asked whether mycolactone interferes with CDC42-mediated activation of WASPs, and vice versa. Mycolactone did not modify the binding of CDC42-GTP to immobilized WASP CR1 or N-WASP CR7 (data not shown). The maximal activation reached by mycolactone-bound N-WASP in actin assembly assays was more pronounced than that induced by CDC42 (Figure 2E). Moreover, the dose-dependent activation of N-WASP induced by mycolactone was independent of the presence of CDC42-GTP.
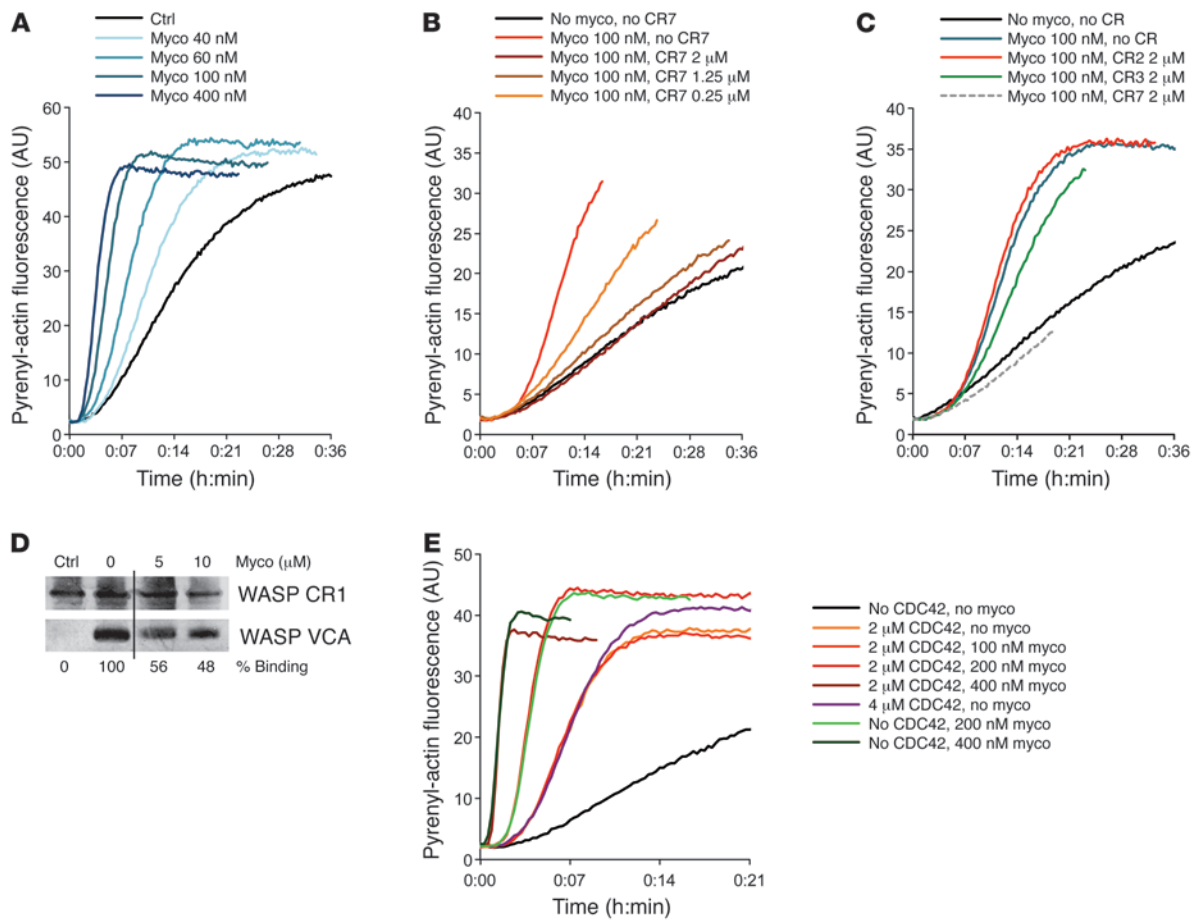

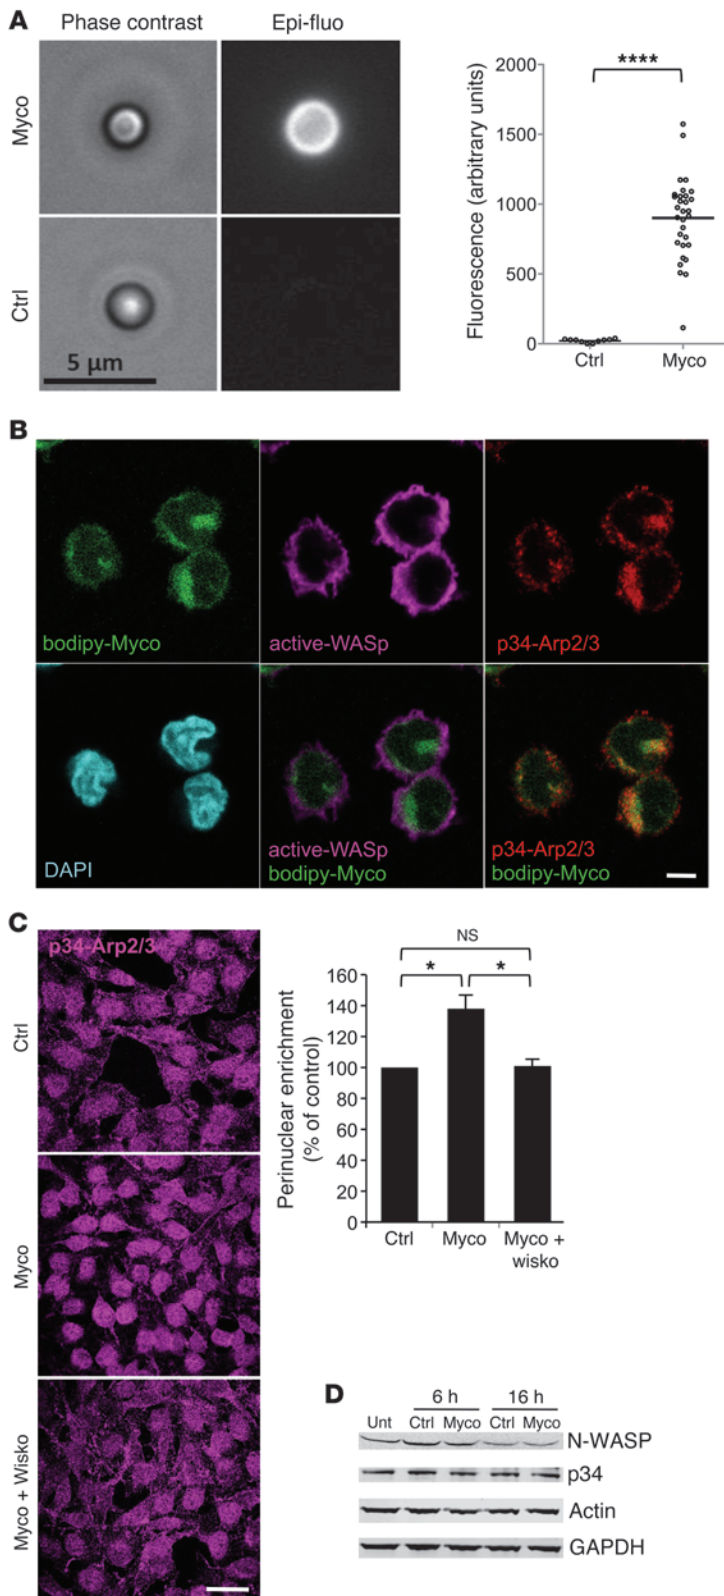

Figure 2
Mycolactone binding to N-WASP potentiates its actin polymerization activity. (**A**) Effect of increasing concentrations of mycolactone on N-WASP–dependent polymerization of pyrenyl actin. Equivalent volumes of solvent were used as control. (**B**) CR7 dose-dependently inhibited mycolactone-induced N-WASP activation. (**C**) Effect of CR2, CR3, and CR7 on mycolactone-induced N-WASP activation. (**D**) Mycolactone dose-dependently displaced CR1-bound VCA. Silver staining of WASP CR1 and VCA, after incubation of GST-fused CR1 (immobilized on glutathione-sepharose beads) with VCA in the presence of increasing amounts of mycolactone, and analysis of bead-bound products by gel electrophoresis. No VCA served as control. Lanes were run on the same gel but were noncontiguous (black line). (**E**) Differential activity of mycolactone and CDC42-GTP (CDC42) on N-WASP–dependent actin polymerization.

Together, these data support the view that a ternary complex can be formed in which CDC42-GTP and mycolactone bind distinct sites on WASPs. Like CDC42, mycolactone activate WASPs by releasing the VCA from the GBD. However, with a 100-fold higher affinity (26), mycolactone is a much stronger activator of N-WASP–mediated actin assembly.

Mycolactone activates cellular WASP/N-WASP to promote actin assembly. To evaluate the physiological relevance of these findings, we then coated latex beads with mycolactone, incubated them with N-WASP, and placed them in Jurkat cell extracts spiked with fluorescently labeled actin. A fluorescent signal readily developed at the surface of mycolactone-coated beads incubated with N-WASP, but not control beads that either had not been coated with mycolactone or had not been incubated with N-WASP (Figure 3A), which demonstrated that N-WASP activated by mycolactone could induce the formation of branched actin filaments in a cellular environment. We then took advantage of a fluorescent derivative of mycolactone to study its distribution in living cells (Supplemental Figure 4 and ref. 27). As shown in Figure 3B, myco-

lactone was distributed primarily in the cytosolic compartment of treated Jurkat cells. A limited, but significant, colocalization with active WASP was observed after 1 hour, using an antibody that preferentially binds the open form of the protein (Figure 3B). Notably, spots of ARP2/3 complex were detected in the area of Bodipy-mycolactone/active WASP colocalization, which indicates that mycolactone reaches the sites of WASP-mediated ARP2/3 activation. After 4 hours, immunofluorescence detection of ARP2/3 revealed an increased level of activated complex in the perinuclear area of HeLa cells (Figure 3C). These alterations persisted for more than 16 hours and were efficiently suppressed by coincubation with the N-WASP inhibitor wiskostatin (28). They were not due to increased protein level, as expression of WASP, N-WASP, the p34 subunit of ARP2/3 (p34-ARP2/3), and actin was unchanged in mycolactone-treated cells (Figure 3D). Taken together, the data in Figure 3 indicated that mycolactone promotes perinuclear recruitment and activation of ARP2/3 by N-WASP.

Activation of N-WASP in epithelial cells mediates mycolactone-induced adhesion defects. Since N-WASP is a major regulator of cell adhesion

ure 4A). If exposure to mycolactone was prolonged over 24 hours, this process culminated in cell rounding and detachment (Figure 4, A and B). Induction of cell apoptosis, as measured by caspase activation (early stages) and membrane permeability to propidium iodide (late stages), was primarily observed in the detached fraction of mycolactone-treated cells (Figure 4C), which strongly suggested that mycolactone kills epithelial cells by anoikis. Strikingly, 4 hours of exposure to mycolactone was sufficient to induce a near-complete and persistent incapacity to adhere to plastic wells (Figure 4D). This effect was counteracted by wiskostatin or by prior transfection of the cells with WASP CR1 (Figure 4, D and E), demonstrating its association with activated N-WASP.

In HeLa cell monolayers treated with mycolactone for 16 hours, cell retraction was associated with a marked reduction in the number of intercellular contacts (Figure 5A). Cadherin staining showed that mycolactone suppressed both the maintenance of mature cell-cell junctions and the active formation of new interfaces via an adhesion zipper (Figure 5B). In polarized systems, such as the MDCK cell line model, mycolactone induced marked suppression of adherens and tight junctions, as shown by the decrease in the fluorescent ring–like signal of cadherins and zona occludens–1 (ZO-1; Figure 5C). Confocal imaging of basal sections revealed decreased stress fibers, increased perinuclear actin rings, and impaired membrane localization of cadherin in mycolactone-treated cells, resulting in disruption of the honeycomb-like organization and, eventually, rupture of the monolayer (Figure 5, D and E).

Mycolactone impairs direction sensing in migrating epithelial cells. The directed migration of epithelial cells requires not only activation

(21, 22), we next explored its contribution to mycolactone effects on cell-cell and cell-matrix contacts. Live imaging of HeLa cells exposed to mycolactone revealed that the early induction of spike-like protrusions was followed by lamellipodium retraction (Fig-
Figure 4

of ARP2/3-mediated actin assembly, but also its localization at the leading edge (29). The potential effect of mycolactone on HeLa cell displacement was therefore evaluated in a wound-healing assay. As shown in Figure 6A, mycolactone-exposed cells had an impaired capacity to close wounds. This was not due to decreased cell motility, as mycolactone-treated cells moved faster than vehicle-exposed controls (Figure 6B). However, the directionality of their movement was altered: cell trajectories were not linear and perpendicular to the wound (*x* axis) like those of control cells, resulting in shorter displacements (Figure 6B). Prior transfection of the cells with WASP CR1 abrogated the mycolactone-induced alterations in speed and directionality and partially restored healing capacity (Figure 6, C and D), which suggests that mycolactone binding to endogenous N-WASP is critically involved in these defects.

Hyperactivation of epithelial N-WASP underpins epidermal rupture. The human epidermis is a stratified squamous epithelium composed of proliferating basal keratinocytes attached to a basement membrane and suprabasal keratinocyte layers at various stages of differentiation (from base to top: spinosum, granulosum, lucidum, and corneum). The maintenance of cell-cell contacts and the directionality of cell migration perpendicularly to the basement membrane have been shown to be critical for the maintenance of skin integrity (reviewed in ref. 30). Since mycolactone-induced activation of N-WASP affects both adhesion and direction sensing of epithelial cells, we investigated its effect on epidermal integrity in the mouse ear model, focusing on the events preceding tissue destruction and ulcer formation (Supplemental Figure 5). As soon as 2 days after injection, we observed progressive thinning of the external stratum granulosum and lucidum (Figure 7, A and B), resulting in a significant decrease in epidermis width after 54 hours (Figure 7C). In agreement with our observation on cultured cells, remodeling of the epidermal layers was associated with a dramatic loss of E-cadherin–adhesive contacts, particularly in the stratum spinosum (Figure 7D). Importantly, coadministration of wiskostatin suppressed mycolactone-induced dissociation and thinning of the epidermis (Figure 7, D and E), demonstrating the importance of N-WASP activation in this process.

Discussion

Here, we showed that mycolactone mimicked endogenous regulators of WASP/N-WASP to hijack ARP2/3-mediated assembly of actin filaments in host cells. Numerous bacterial effectors, such as IcsA/VirG of *Shigella flexneri* (31) and TccP/EspFu of the enterohemorrhagic *Escherichia coli* (32), target WASP/N-WASP in host cells. However, mycolactone is the first example of a nonprotein factor interfering with these actin-nucleating factors. Unlike IcsA and EspFu, which require translocation into target cells, mycolactone gains access to WASPs by passive diffusion through the plasma membrane (8). Mycolactone bound N-WASP 100-fold more

strongly than its major regulator, CDC42 (26), leading to a much greater capacity to stimulate actin assembly in vitro. The ARP2/3 complex has previously been shown to induce a slight shift in the autoinhibitory equilibrium of WASP, facilitating CDC42-induced opening and activation (26). We found that ARP2/3 comparably potentiated mycolactone-induced release of WASP CR1–bound VCA (data not shown). This property, combined with its high affinity for WASPs, should enable mycolactone to efficiently disconnect WASPs from endogenous regulation in vivo.

Mycolactone counteracted the effects of the N-WASP inhibitor wiskostatin in cellular assays. Consistent with the fact that wisko-

statin inhibits N-WASP activity by stabilizing the autoinhibited conformation, we found that mycolactone relieves the intramolecular contacts that maintain WASP autoinhibition. Intriguingly, mycolactone binding to WASPs involved the BR, which is located immediately upstream of the CRIB. Phosphatidylinositol 4,5-disphosphate (PiP₂) micelles react with arginine and lysine residues clustered in this region to activate WASPs at both the allosteric level and the oligomerization level (33). NMR studies will help to determine whether mycolactone exploits this mechanism and to provide structural insight into the hyperactive conformation of the mycolactone–N-WASP complex.

In HeLa cells exposed to mycolactone, ARP2/3 was primarily detected in the perinuclear area, which suggests that mycolac-

tone-induced activation of N-WASP operates preferentially in this region. Accordingly, the defects caused by mycolactone in migrating epithelial cells (e.g., increased speed of cell migration and loss of directionality) were comparable to those induced by delocalization of ARP2 expression from leading protrusions to the perinuclear area (34). The decreased capacity of mycolactone-exposed cells to extend cadherin-adhesive contacts was similar to that previously observed upon sequestration of ARP2/3 by exogenously expressing the CA region of N-WASP (35).

Our data in Figure 4 showed that mycolactone-induced killing of epithelial cells was primarily caused by N-WASP–mediated detachment and subsequent anoikis. This mechanism obviously

cannot explain mycolactone cytotoxicity in anchorage-independent cells, such as T lymphocytes (11). Activating mutations in WASP have been shown to increase apoptosis in T cells by promoting genomic instability, providing a possible mechanism for the mild cytopathic activity of mycolactone in this cell population (36). With regard to its immunomodulatory properties, recent studies indicating that WASP is an epigenetic regulator of Th1 gene expression suggest that it may be involved in mycolactone inhibition of cytokine production by T cells (37). Our observation that mycolactone induced lamellipode formation in T cells (Figure 1A) strongly suggests that it may also alter the T cell spreading response to activation. Contrary to N-WASP, WASP is essential and can be silenced without a major effect on viability. Study of animal models deficient for WASP expression or expressing WASP

mutants that are unable to bind mycolactone should help to dissect the contribution of this key immune regulator to mycolactone activity in the hematopoietic cell compartment.

Currently available techniques do not allow for precise quantification of mycolactone concentration in infected tissues (38, 39). We chose to inject 5 μg mycolactone into mouse ears, as within 2 weeks, this dose reproduces the characteristic lesions developing after months in mice infected with *M. ulcerans* (40). Consistent with our observation that mycolactone suppressed cell-cell contacts in polarized epithelia (Figure 5), our histopathological analysis of mycolactone-injected skin revealed profound alterations in E-cadherin junctions and epidermal architecture, which suggests that uncontrolled activation of N-WASP impairs epithelial differentiation in this tissue. Since mycolactone-induced thinning of the skin was suppressed by wiskostatin, we propose that hyperactivation of N-WASP (and consequent dissociation of epithelial cells) is the primary cause of epidermal destruction in Buruli ulcers.

Pathogens often modulate the host actin cytoskeleton to enhance their propagation and survival (41). *M. ulcerans* does not survive at the core temperature of the human body and multiplies extracellularly in disintegrated skin tissues. This environment, and the associated release of nutrients by dead cells, may constitute a favorable niche for the growth of *M. ulcerans* in an infected host. By targeting WASP and N-WASP, mycolactone has the potential to affect the functional biology of both immune and nonimmune cell populations. Further investigations will be required to determine whether WASP-mediated functions are altered by mycolactone in hematopoietic cells, and to what extent these alterations contribute to the immune defects of *M. ulcerans*–infected hosts.

Our present results suggest that modulation of mycolactone-induced N-WASP activation in the skin might counteract the ulcerative effects of mycolactone and represent a viable strategy to treat Buruli ulcers. This hypothesis was supported by preliminary results showing that local injection of wiskostatin limited the epidermal remodeling preceding ulceration in *M. ulcerans*–infected mice (our unpublished observations). Resolving the structure of the mycolactone/WASP complex should identify the contact amino acids. Drugs mimicking the binding site of mycolactone in WASP may represent inhibitors of interest for treating this debilitating human disease (42).

Methods

Reagents. Mycolactone was purified from *M. ulcerans* 1615 (ATCC 35840) and quantified as described previously (4, 43). Stock solutions were prepared in methanol. Wiskostatin (Sigma-Aldrich) was in DMSO. Both reagents were diluted at least ×10 in PBS before injection in animals and at least ×1,000 in culture medium for cellular assays. In all cases, mycolactone- and wiskostatin-treated samples were compared with vehicle-treated controls.

WASP and N-WASP constructs. The CR1–CR7 constructs corresponding to WASP/N-WASP domains were provided by C. Egile (Institut Pasteur) or generated in our laboratory. The CR8–CR11 constructs were derived from N-WASP CR7 for the purpose of this study. The WASP VCA construct was provided by M.K. Rosen (University of Texas Southwestern Medical Center, Dallas, Texas, USA). GST-tagged WASP/N-WASP and His$_6$-tagged VCA constructs were produced in BL21 *E. coli* according to standard induction and purification procedures. Human N-WASP was expressed in Sf9 cells using the baculovirus system.

Cell cultures and viability assays. HeLa cells and Jurkat E6.1 T cells (referred to herein as Jurkat cells) were cultured in DMEM and RPMI 1640 medium (Invitrogen), respectively, supplemented with 10% heat-inactivated FCS

(Invitrogen) and 2 mM L-glutamine (Sigma-Aldrich). Micropatterns were purchased from Cytoo, and cell plating was performed as recommended by the manufacturer. When appropriate, wiskostatin was added to HeLa cells at a final concentration of 1 μM for 24 hours. This low-dose treatment had no detectable effect on cytokinesis or ATP levels (data not shown and refs. 44, 45). The induction of early/late cell apoptosis was determined by flow cytometry using the Poly-Caspases Flica assay (Immunochemistry) and Sytox-green nucleic acid stain.

Immunofluorescence microscopy. Cells were fixed for 15 minutes at room temperature (RT) with PBS plus 3% paraformaldehyde, washed with PBS, and incubated with NH$_4$Cl (50 mM) in PBS for 10 minutes at RT, prior to incubation with primary and secondary antibodies in PBS plus 5% BSA and 0.05% saponin for 1 hour at RT. Actin was labeled with rhodamine phalloidin, cadherin with anti–pan-cadherin mouse monoclonal CH-19 (Sigma-Aldrich), ZO-1 with rabbit polyclonal 61-300 (Zymed), and N-WASP with guinea pig polyclonal antibody (provided by M.D. Welch, University of California, Berkeley, California, USA). Cell areas and junctions were measured manually on Image J pictures of actin/cadherin-stained cells. For colocalization studies, Jurkat T cells were stained with 26E6 anti-WASP monoclonal Ab (provided by J.K. Burkhardt, University of Pennsylvania, Philadelphia, Pennsylvania, USA), which is specific for the active form of the protein. WASP and Bodipy-mycolactone fluorescence signals were deconvoluted with Huygens professional software (Scientific Volume Imaging), and colocalization was analyzed by calculating the Pearson coefficient with the Jacop plugin of ImageJ, using Costes's automatic threshold method (46, 47). For ARP2/3 staining, HeLa cells were fixed with 4% paraformaldehyde in cytoskeletal stabilization buffer (10 mM PIPES, pH 6.8; 100 mM KCl; 300 mM sucrose; 2 mM EGTA; and 2 mM MgCl$_2$) for 20 minutes, then permeabilized with 0.25% Triton X-100 in PBS for 10 minutes at RT. Cells were stained with a rabbit anti–p34-Arc/ARPC2 polyclonal antiserum (1:400 dilution; Upstate) and anti-rabbit Cy3 (1:800 dilution), both in PBS plus 1% BSA. Image analysis was performed with a custom-designed script developed using Acapella Image analysis software (version 2.5; Perkin Elmer). This script was based on nuclei segmentation, allowing the definition of a perinuclear ring of fixed thickness (6 pixels). For each nucleus ($n > 50$), the intensity of p34-ARP2/3 staining per unit of ring surface was calculated and integrated on 4 consecutive z sections (0.45 μm), then exported in a readable file format for statistical analysis.

Actin polymerization assays. Actin was purified from rabbit skeletal muscle (48), and the monomeric G form was purified by gel filtration and labeled with pyrenyl iodoacetamide or Alexa Fluor 488 succinimidyl ester (Invitrogen). The ARP2/3 complex was purified from bovine brain (31). The time course of actin polymerization was monitored spectrofluorometrically in a Safas Xenius instrument using the increase in pyrenyl actin fluorescence as a probe, with excitation and emission wavelengths of 366 and 407 nm, respectively. Polymerization was assayed at 2.5 μm G-actin (5% pyrenyl labeled), with 28 nm ARP2/3 complex and 32 nm N-WASP in the presence of mycolactone or solvent as control. The buffer contained 5 mM Tris-Cl (pH 8), 0.2 mM ATP, 0.1 mM CaCl$_2$, 0.1 M KCl, 1 mM MgCl$_2$, and 0.2 mM EGTA. When required, CDC42 was loaded with GTP-gS by a 30-minute incubation at RT with 1 mM GTP-gS in 5 mM EDTA. For actin polymerization on beads, streptavidin-latex 2-μm beads were incubated with 12.5 μM biotinylated mycolactone (or vehicle as control) for 15 minutes, rinsed, incubated with 400 nM N-WASP for 30 minutes (or buffer as control), rinsed, placed into Jurkat cell homogenates spiked with 1.5 μM G-actin (10% Alexa Fluor 488) plus 1.2 mM ATP and 2.4 mM MgCl$_2$, and analyzed for fluorescence after 2 hours at RT.

Cell adhesion assays. We used the Vybrant calcein-AM–based assay of cell adhesion (Molecular Probes). Briefly, HeLa cells grown in microplate wells were treated with mycolactone or vehicle, then detached and loaded with the cytoplasmic marker calcein-AM. Labeled cells were then left to adhere

to microplate wells for 2 hours, after which the nonadherent fraction was removed. The number of adherent cells was derived from the intensity of calcein fluorescence in each well.

Wound-healing assays. Wound-healing assays were performed with culture inserts and μ-slide 8 wells from Ibidi. Briefly, HeLa cells (70 μl, 5 × 10⁵ cells/ml) were seeded in culture inserts and incubated for 24 hours at 37°C. After removal of culture inserts, cells were washed 3 times in ×1 PBS and resuspended in 300 μl fresh DMEM/F-12 supplemented with 10% FCS and 2 mM L-glutamine. Cell migration was recorded for 24 hours at 37°C using a Nikon Eclipse Ti, capturing images at 10-minute intervals. Cell tracking was performed with Imaris (version 6.0; Bitplane).

Histology and immunocytochemistry. C57BL/6J mice were purchased from Jackson Laboratories and bred under specific pathogen–free conditions. Animals were injected intradermally in the center of the ear with the indicated reagents in a 50 μl PBS volume. At the indicated time points, mice were killed, and the ears were surgically removed and divided into 2 halves. One was fixed, dehydrated with absolute ethanol, plastic resin embedded (Historesin Leica MicroSystem), and processed for H&E staining. The other was snap frozen in isopentane cooled with liquid nitrogen before 5-μm cryosectioning and immunostaining with rat anti-mouse E-cadherin ECCD-2 (Invitrogen) followed by secondary antibodies (Jackson Immuno-Research). Nuclear DNA was visualized by Topro3 (Invitrogen).

Statistics. For each statistical comparison, the test used, *n*, and respective *P* value is provided in the corresponding figure legend.

Study approval. All experiments were performed in accordance with the guidelines of the National French Veterinary Department.
